ABSTRACT

The significance of Northern China in the budget of atmospheric trace gases is discussed briefly. Sites for the research work of the IGBP/IGAC Activity 7.2 and some results of preliminary measurements on N\textsubscript{2}O flux are also introduced.

In China, 6 sites along 40°N have been identified as contributors to research efforts described by IGBP/IGAC Activity 7.2. These sites are located in forest, grassland, agriculture, arid and semi-arid and desert regions. On one of these sites, the Luancheng Comprehensive Experimental Station of Agricultural Ecology, the flux of N\textsubscript{2}O on a typical, winterwheat field was measured. Measurements were taken during the growing season of winterwheat in both fertilized and unfertilized fields. Measurements were also taken in an alfalfa fields. It was shown that fertilization, irrigation and soil temperature were positively related to the emission of N\textsubscript{2}O. The diurnal variability of fluxes was measured. The fluxes in different treatments varied from 2-46 µg N m\textsuperscript{-2}h\textsuperscript{-1}.

1. INTRODUCTION

Nitrous oxide is one of the most important long-living greenhouse gases, and, in addition, is the primary source of oxides of nitrogen in the stratosphere, which, along with chlorofluorocarbons, play a critical role in controlling the abundance and distribution of stratospheric ozone. The atmospheric concentration of nitrous oxide is about 310 ppbv with

a rate of increase of 0.2-0.3% per year (WMO, 1992). This represents an annual atmospheric growth rate of about 3 to 4.5 TgN. Since the total annual emission rate of nitrous oxide appears to be in the range of 10-17.5 TgN, as deduced from the magnitude of its sinks, and its rate of accumulation in the atmosphere and the estimated annual sources are between 5.2 and 16.1 TgN (Houghton et al., 1992), it seems that the emission rates of some of the identified sources have been underestimated or that there are some unidentified sources. It has been suggested that land-use change and agricultural development may stimulate N2O production in soils and account for some of the principal missing emissions (Bouwman, 1990). Additionally, the agricultural areas of the mid-latitudes may be making significant contributions to the observed increases, or even to the unestimated part of the sources.

2. EXPERIMENTAL SITES FOR TRACE GAS EXCHANGE STUDY IN NORTHERN CHINA

Northern China, located around 40°N and between 75° and 135°E, includes a variety of temperate ecosystems. Having a long history of development lasting thousands of year, this region has undergone extensive land-use change and agricultural practices. However, extensive changes during the last century are evident. In the past fifty years, agricultural changes related to fertilization, irrigation and new crop varieties have contributed to marked increases in grain production. All of these play an important role in the changes of sources and sinks of trace gases, especially CH4, N2O and CO2. There is a need for basic emission data of trace gases, for studies on trace gas exchange in this region and for global budget and environmental impact research. However, in the vast area of Northern China, there have been very few research studies on N2O emission and very limited data are available (Su et al., 1989, 1990, 1992).

The Chinese Academy of Sciences runs the Chinese Ecological Research Network consisting of more than fifty ecological stations covering important natural, semi-natural and ecotone ecosystems all over the country. In this Network, six sites along 40°N have been identified as contributors to research efforts described by IGBP/IGAC Activity 7.2: Trace Gas Exchange: Mid-Latitude Terrestrial Ecosystems and Atmosphere. These sites are located in forest, grassland, agriculture, arid and semiarid, and desert regions as shown in Figure 1 and Table 1.

3. MEASUREMENT OF N2O FLUX ON A WINTERWHEAT FIELD—A PRIMARY FLUX STUDY AT MID-LATITUDE OF CHINA

This work took a site on a winterwheat field as an experimental site for N2O flux measurement since winterwheat is a main crop in Northern China. This site is located at the Luancheng Comprehensive Station of Agricultural Ecology, Institute of Agriculture Modernization, the Chinese Academy of Sciences (Shijiazhuang, Province Hebei, 37°54'N, 114°42'E). Measurements were made on two kinds of winterwheat fields: unfertilized and fertilized with 120 kg N ha⁻¹ year⁻¹, and also on two kinds of alfalfa fields: unfertilized and fertilized with 120 kg N ha⁻¹ year⁻¹. In spring after winterwheat turned green, flux measurements were performed on the fields after being fertilized and irrigated, during the earing and mature stages of winterwheat, and they were compared with those in the alfalfa fields.

The sampling instrumentation consisted of a sealed box (1 m x 1 m x 1 m) placed on the fields. The walls and the top of the box were made of teflon film produced by the Du Pont Company. There was a sampling vent on the side of box. The gas sample was drawn into a sampling bag from a sampling box by a miniature air pump. The sampling bags were made of aluminium-plated film with a 1-litre volume. Meteorological and soil temperature data were recorded. In this paper, soil temperatures always refer to those at 10 cm below surface. The gas samples were analysed on an SP-3410 gas chromatography apparatus with an Ni63 electron capture detector.
N$_2$O flux (F) - N$_2$O mass released from land into the atmosphere per unit area per unit time - is a synthetically macroscopical value consisting of many factors. It can be expressed by:

$$F = \frac{(m_2 - m_1)}{A(t_2 - t_1)}(\mu g \ m^{-2}hr^{-1})$$  \hspace{1cm} (1)

where $m_1$ and $m_2$ are N$_2$O mass ($\mu g$) inside the box volume V ($m^3$) at time $t_1$ and $t_2$ respectively; A is the bottom area of the sampling box ($m^2$);

$$m_1 = Vc_1d, \quad m_2 = Vc_2d(\mu g)$$  \hspace{1cm} (2)

where $d$ is the mass density of N$_2$O ($\mu g/m^3$); $c_1$ and $c_2$ are the volume mixing ratios of N$_2$O at time $t_1$ and $t_2$ (ppb), respectively, thus:

$$F = Hd(c_2 - c_1)/(t_2 - t_1)(\mu g/m^3hr),$$  \hspace{1cm} (3)

where H(=V/A) is the height of the sampling box.

After the winterwheat turned green, measurements were performed on different farming practices (fertilization, irrigation) and at different growth stages (earing, mature, harvest). The results of these investigations follow.

In the unfertilization stage, the N$_2$O fluxes of the winterwheat and alfalfa fields were 2 and 3 $\mu g$ N m$^{-2}$hr$^{-1}$ respectively, but those of fertilized fields were above 20 (winterwheat) and 22 (alfalfa) $\mu g$ N m$^{-2}$hr$^{-1}$, respectively. This means with more nitrogen sources in the soil, the N$_2$O flux became higher, and on neighbouring fields with the same soil nature and under similar farming practices, the N$_2$O fluxes of the winterwheat and alfalfa fields were close. This shows that biological-chemical processes play a dominant role in the production process of N$_2$O.

Soil moisture has a certain influence upon N$_2$O releases. Three days after the winterwheat field was irrigated, flux became relatively high as shown in Figure 2, reaching a maximum of 46 $\mu g$ N m$^{-2}$hr$^{-1}$.

![Figure 2](image-url)  
St1-Before irrigation, St2-After irrigation  
*Fig. 2. N$_2$O fluxes before and after the irrigation of the winterwheat field.*
The diurnal variations in the N$_2$O fluxes of the fertilized and unfertilized winterwheat fields were observed. The diurnal variation in the N$_2$O flux on the fertilized winterwheat field shows that during the earing stage, it was high in the daytime but low at night. Flux varies with soil temperature (see Figure 3), with its maximum (30 $\mu$g N m$^{-2}$ hr$^{-1}$) occurring after midday when the soil temperature was the highest (17°C). However, its minimum (5 $\mu$g N m$^{-2}$ hr$^{-1}$) occurred after midnight when the soil temperature was low (12°C). As to the unfertilized winterwheat field, there were similar circumstances, the maximum of flux (18$\mu$g N m$^{-2}$ hr$^{-1}$) occurring in the daytime, and its minimum at night (see Figure 4).

**Fig. 3.** The diurnal variability of N$_2$O fluxes (□) and soil temperature on the fertilized farmland in the earing stage of winterwheat (1990.6.4-6).

**Fig. 4.** The diurnal variability of N$_2$O fluxes (□) and soil temperature on the fertilized farmland in the earing stage of winterwheat (1990.5.4-5).
The diurnal variations in flux of the winterwheat fertilized field during the mature stage are shown in Figure 5. The pattern here is similar to that during the earing stage. All of the flux values were below 14 $\mu g \text{N m}^{-2}\text{hr}^{-1}$ (27°C), which were lower than those of the earing stage. After harvest, the variation in flux was basically irregular. Fluxes were lower than or close to the values before harvest, though soil temperature after harvest was apparently higher than those temperatures during other growth stages of winterwheat.

All of the above mentioned indicates that the $N_2O$ fluxes of the fields during different growth periods were different. According to Figure 6, beginning when the winterwheat turned green, the flux on the third day after fertilization was about 20 $\mu g \text{N m}^{-2}\text{hr}^{-1}$, with an average soil temperature of 9.2°C; flux on the third day after irrigation reached the maximum of about 46 $\mu g \text{N m}^{-2}\text{hr}^{-1}$; flux of the unfertilized field reached 15 $\mu g \text{N m}^{-2}\text{hr}^{-1}$ too. This indicates an increase in soil moisture is advantageous to $N_2O$ release in biological-chemical processes. If there are sufficient nitrogen sources and suitable soil moisture, the rise in temperature is also advantageous to the increase in flux. During the earing stage of winterwheat, the mean fluxes of fertilized and unfertilized fields were 17 and 12 $\mu g \text{N m}^{-2}\text{hr}^{-1}$ respectively, with a mean soil temperature of 16°C. During the mature stage, the averaged value of fluxes in the fertilized field was 8 $\mu g \text{N m}^{-2}\text{hr}^{-1}$, though the mean soil temperature was 23.3°C. After harvest, although the mean soil temperature reached the high value of 24.3°C, the averaged flux value was only 6 $\mu g \text{N m}^{-2}\text{hr}^{-1}$.

All of these results show that the application of nitrogen fertilizer may be a primary factor in the increase in $N_2O$ flux on the basis of $N_2O$ release from bio-chemical processes. If soil moisture increases and soil temperature rises too, more $N_2O$ fluxes from soil moisture. During the growth processes of winterwheat, the $N_2O$ flux fell as the nitrogen content in the soil was consumed by plant growth. Fluxes during the earing and mature stages tended to decrease though the soil temperature was considerably high. The reason that flux after harvest was very small may be that the nitrogen content in the soil was exhausted and then the $N_2O$ emission was basically a result of its natural releases from the soil.

releasing process in which oxygen is involved. Compared with the denitrification process, the nitrification process is not a main reaction of the production of crucial influence on chemicals in the middle stage of the conversion process of process and the production of by the nitrification processes:

\[
\text{NH}_3 \rightarrow \text{NH}_4^+ \rightarrow \text{NO}_2^- \rightarrow \text{NO}_3^-
\]

but amine produced in the middle stage of the conversion process of \(\text{NH}_4^+\) into \(\text{NO}_2^-\) can be converted into \(\text{N}_2\text{O}\) by microbiological and chemical denitrification processes:

\[
\text{NH}_4^+ + \text{O}_2 \rightarrow \text{NH}_2\text{OH} \rightarrow \text{NOH} \rightarrow \text{NO}_2^- \\
\rightarrow \text{N}_2\text{O} + \text{NO}
\]

Ventilation, oxygen supply and heat dispersion of soil are conditions conducive to for the production of \(\text{N}_2\text{O}\) through nitrification since the nitrification process is an energy-releasing process in which oxygen is involved. Compared with the denitrification process, the nitrification process is not a main reaction of the production of \(\text{N}_2\text{O}\) in soil.

Consequently, fertilization, irrigation or precipitation and soil temperature have some crucial influence on \(\text{N}_2\text{O}\) flux. During the whole growth process of winterwheat, the differences in \(\text{N}_2\text{O}\) fluxes are very large, even larger than the order of one. Table 2 includes some

published data on N$_2$O fluxes on different croplands. Apparently, soils nurturing these crops as well as farming practices, such as fertilization and irrigation, differ from each other very much, and consequently, it is not easy to get a reliable and reasonable mean value of N$_2$O flux for climate and environment research.

Therefore, it is necessary to deliberate thoroughly and to perform research work carefully on such problems as: the methods and reasonableness of mean value calculations for N$_2$O fluxes during different stages in the growth process of a crop; the synthetic comparability of various data obtained from different crops, lands and farming practices; etc. It is suggested that future studies include the study of flux problems on typical land and crops; the accumulation of data; processing data by reliable mathematical statistical methods. It is also necessary to measure fluxes of other gaseous nitrogen compounds and to probe their production mechanisms so as to provide more thorough scientific basis for environment and climate research.

4. CONCLUSION

(1) For the contribution to research efforts described by the IGBP/IGAC Activity 7.2, six sites in the Mid-Latitude Region (along 40°N, between 75°-135°E) of Northern China were identified. These sites are located in forest, grassland, agriculture, arid and semiarid, and desert regions and are used for comprehensive research in the atmospheric terrestrial exchange of trace gases, eco-environmental change and impact.

(2) N$_2$O fluxes between soil and atmosphere on winterwheat and alfalfa farmland were measured at the Luancheng Comprehensive Station of Agricultural Ecology, located in a typical production region of winterwheat in Northern China. When winterwheat and alfalfa are grown in the same field, their fluxes are close to each other.

(3) Fluxes in different growth stages of winterwheat are different from each other. fertilization, irrigation, soil temperature, etc. may be important control factors in the N$_2$O
produciton in soil. Fluxes exist in the range of 2-46 $\mu g$ N m$^{-2}$hr$^{-1}$ for the whole growth process of winterwheat.
